Since the famous paper of E. Lorenz in 1963 numerical computations using computers play a central role in order to display and analyze solutions of nonlinear dynamical systems. By these means new structures have been emphasized like hyperbolic and/or strange attractors. However theoretical proofs of their existence are very difficult and limited to very special linear cases. Computer aided proofs are also complex and require special interval arithmetic analysis. Nevertheless, numerous researchers in several fields linked to chaotic dynamical systems are confident in the numerical solutions they found using popular software and publish without checking carefully the reliability of their results. In the simple case of discrete dynamical systems (e.g. Hénon map) there are concerns about the nature of what a computer find out : long unstable pseudo-orbits or strange attractors? The shadowing property and its generalizations which ensure that pseudo-orbits of a homeomorphism can be traceable by actual orbits even if rounding errors are not inevitable are not of great help in order to validate the numerical results. Continuous dynamical systems (e.g. Chua, Lorenz, Rössler) are even more difficult to handle in this scope and researchers have to be very cautious to back up theory with numerical computations. We present a survey of the topic based on these, only few, but well studied models.

To appear in: "From Laser Dynamics to Topology of Chaos," (celebrating the 70th birthday of Prof Robert Gilmore, Rouen, June 28-30, 2011), Ed. Ch. Letellier.

1. Introduction

Since the famous paper of E. Lorenz in 1963¹, numerical computations using computers play a central role in order to display and analyze solutions of nonlinear dynamical systems. By these means new structures have been emphasized like hyperbolic and/or strange attractors. However theoretical proofs of their existence are very difficult and limited to very special linear cases.² Computer aided proofs are also complex and require special interval arithmetic analysis.^{3,4} Nevertheless, numerous researchers in several fields linked to chaotic dynamical systems are confident in the numerical solutions they found using popular software and publish

without checking carefully the reliability of their results. In the simple case of discrete dynamical systems (*e.g.* Hénon map⁵) there are concerns about the nature of what a computer find out : long unstable pseudo-orbits or strange attractors?⁶ The shadowing property which ensures that pseudo-orbits of a homeomorphism can be traceable by actual orbits, even if rounding errors are not inevitable, is not a great help in order to validate the numerical results.⁷ Continuous dynamical systems (*e.g.* Chua, Lorenz, Rössler) are even more difficult to handle in this scope and researchers have to be very cautious to back up theory with numerical computations.^{8,9} We present a survey of the topic based on these, only few, but well studied models.¹⁰

In Sec. 2 we define the paradigm for possibly flawed computations: continuous and discrete chaotic dissipative dynamical systems. In Sec. 3, some undesirable collapsing effects are highlighted for an example of strange attractor and for 1-dimensional discrete dynamical systems (logistic and tent maps). The shadowing properties (parameter-shifted, orbit-shifted shadowing) are presented in Sec. 4, together with the classical mappings of the plane into itself: the Hénon and Lozi maps. Finally in Sec. 5 the case of the seminal Lorenz model and its following metaphors: Rössler and Chua equations is examined.

2. Continuous and discrete chaotic dissipative dynamical systems: a paradigm for possibly flawed computations

2.1. *Some classes of dynamical system*

Dynamical systems are involved in the modeling of phenomena which evolve in time. Their theory attempts to understand, or at least describe in form of mathematical equations, the changes over time that occur in biological, chemical, economical, financial, electronical, physical or artificial systems. Examples of such systems include the long-term behavior of solar system (sun and planets) or galaxies, the weather, the growth of crystals, the struggle for life between competing species, the stock market, the formation of traffic jams, etc.

Dynamical systems can be continuous *vs* discrete, autonomous *vs* non-autonomous, conservative *vs* dissipative, linear *vs* nonlinear, etc. When differential equations are used, the theory of dynamical systems is called continuous dynamical systems. Instead when difference equations are employed the theory is called discrete dynamical systems. Some situations may also be modeled by mixed operators such as differential-difference equations. It is the theory of hybrid systems.

In mathematics, an autonomous system or autonomous differential equation is a system of ordinary differential equations which does not explicitly depend on the independent variable, if it is not the case the system is called non-autonomous.

Classical mechanics deals with dynamical systems without damping or friction as the ideal pendula, the solar system. In this case the dynamical systems involved are conservative dynamical systems. When damping or friction occur the dynamical systems are dissipative.

Linear dynamical systems can be solved in terms of simple functions and the behavior of all orbits classified, on the contrary there are in general no explicit solutions of non linear dynamical systems which model more complex phenomena.

Before the advent of fast computing machines, solving a non linear dynamical system required sophisticated mathematical techniques and could be accomplished only for a small class of dynamical systems. Numerical methods implemented on computers have simplified the task of determining the orbits of a dynamical system. However when chaotic dynamical systems are studied the crucial question is: can we rely on these solutions ?

Chaos theory studies the behavior of dynamical systems that are highly sensitive to initial conditions, an effect which is popularly referred to as the butterfly effect. Small differences in initial conditions (such as those due to rounding errors in numerical computation) yield widely diverging outcomes for chaotic systems, rendering long-term prediction impossible in general. This happens even though these systems are deterministic, meaning that their future behavior is fully determined by their initial conditions, with no random elements involved. In other words, the deterministic nature of these systems does not make them predictable. The first example of such chaotic continuous system in the dissipative case was pointed out by the meteorologist E. Lorenz in 1963.¹

In this article we limit our study to chaotic (hence non linear) dissipative dynamical systems, either continuous or discrete, autonomous or non-autonomous. The case of linear system is not relevant because most of the solutions are given by closed formulas. The case of conservative system is much more difficult to handle as the lack of friction (dissipation of energy) leads to exponential increasing of rounding errors. Dedicated techniques are necessary to obtain reliable solution.¹¹

Although there exist peculiar mathematical tools in order to study non-autonomous dynamical systems, they can be easily transformed in autonomous systems increasing by one the dimension of the space variable. Then we only consider autonomous systems. We focus our study to the most popular models: for the discrete case: logistic and tent map in 1-dimension, Hénon and Lozi map in 2-dimension; for the continuous case: Lorenz, Rössler and Chua model.

2.2. Poincaré map: a bridge between continuous and discrete dynamical system

Generally (*i.e.* when there exist a periodic solution) the Poincaré map allows us to build a correspondence between continuous and discrete dynamical systems. If we consider a 3-dimensional continuous dynamical system (*i.e.* a system of three differential autonomous equations):

$$\begin{cases} \dot{x}_1 = f_1(x_1, x_2, x_3) \\ \dot{x}_2 = f_2(x_1, x_2, x_3) \\ \dot{x}_3 = f_3(x_1, x_2, x_3) \end{cases} \quad (1)$$

Figure 1. Solutions of a differential system in \mathbb{R}^3 .

the solution of such a system can be seen as a parametric curve $(x_1(t), x_2(t), x_3(t))$ in the space \mathbb{R}^3 . A periodic solution (also called a cycle) is no more than a loop in this space as shown on Fig. 1 for the solution starting from, and arriving to, the same initial condition X_0 .

Poincaré map defined in a neighborhood of this cycle is the map φ of the plane $\Sigma = \mathbb{R}^2$ into itself which associates to the initial point belonging to this plane, the first return point of the solution starting from this very initial point $\varphi : X \in \Sigma \rightarrow \varphi(X) \in \Sigma$ (e.g. on Fig. 1. the first intersection point X_2 of the plane Σ with the solution starting from X_1 , $\varphi : X_1 \in \Sigma \rightarrow \varphi(X_1) = X_2 \in \Sigma$). Then the study of n -dimensional continuous system is equivalent to the study of $(n - 1)$ -dimensional discrete system.

Figs. 2 and 3 display the discrete periodic orbit $\{X_0, X_1, X_2, X_3, X_4 = X_0\}$ associated to the continuous periodic orbit of period 4:

$$\varphi^{(4)}(X_0) = \varphi \circ \varphi \circ \varphi \circ \varphi(X_0) = X_0$$

3. Collapsing effects

3.1. Undesirable chaotic transient

In 2008, Z. Elhadj and J. C. Sprott¹² introduced a two-dimensional discrete mapping with C^∞ multifold chaotic attractors. They studied a modified Hénon map given by:

Figure 2. Discrete periodic orbit associated to the continuous periodic orbit of period 4.

Figure 3. Continuous period 4 orbit.

$$f(x_n, y_n) = \begin{pmatrix} x_{n+1} \\ y_{n+1} \end{pmatrix} = \begin{pmatrix} 1 - a \sin(x_n) + by_n \\ x_n \end{pmatrix} \tag{2}$$

where the quadratic term x^2 in the Hénon map (see Sec. 4) is replaced by the nonlinear term $\sin x$. They studied this model for all values of a and b . The essential motivation for this work was to develop a C^∞ mapping that is capable of generating chaotic attractors with “multifolds” via a period-doubling bifurcation route to chaos which has not been studied before in the literature.

They prove the following theorem on the existence of bounded orbits

Theorem 3.1. (*Elhadj & Sprott*) *The orbits of the map (2) are bounded for all $a \in \mathbb{R}$, and $|b| < 1$, and all initial conditions $(x_0, x_1) \in \mathbb{R}^2$.*

The existence of chaotic attractors is only inferred numerically. They display four examples, convincing at first glance, of what they call “chaotic multifold attractors”. Unfortunately one of it obtained for $a = 4.0$ and $b = 0.9$ (Fig. 4) is no more than a long transient regime which collapses to a trivial and degenerate behavior: a periodic orbit of period 6 when the computation is done for sufficiently large value of n . When programming in Language C (Borland[®] compiler), using a computer with Intel DuoCore2 processor and computing with double precision numbers, from any initial points after a transient regime for approximately 110,000 iterates (actually the length of the transient regime depends upon the initial value) the orbit is trapped to the period-6 attractor given by:

$$\begin{aligned} x_{120003} &= 8.95855079898761453 = x_{120009} = x_{120015} = \dots, \\ x_{120004} &= 10.96940289429559630 = x_{120010} = x_{120016} = \dots, \\ x_{120005} &= 13.06132591362670500 = x_{120011} = \dots, \\ x_{120006} &= 8.97249334266406962 = \dots, \\ x_{120007} &= 11.90071070225514802 = \dots, \\ x_{120008} &= 13.07497800339342220 = \dots \end{aligned}$$

This attractor is showed on Fig. 5.

Remark 3.1. It is obvious that the phase space (x_n, x_{n+1}) on which the points $(x_n, x_{n+1}) \in \mathbb{R}^2$ are computed is finite when finite arithmetic replaces continuum state spaces and one can object that every orbit of a mapping must be periodic in this finite space. However with double precision numbers for each component, it is generally possible (in presence of chaotic attractor) to obtain periodic orbit with period as long as 10^{11} (see Lozi map in Sec. 4.2) which could be a good approximation for the attractor. Instead an attracting period-6 orbit has a very different behavior than a strange attractor because such orbit does not possess the sensitivity to initial condition property, which is a minimal necessary condition (but not a sufficient one) of existence of chaos.

This example of long chaotic transient regime hiding a periodic attractor with a very short period is not unique in scientific literature, numerous researchers in

Figure 4. Chaotic multifold attractor of the map (2) for $a = 4.0$ and $b = 0.9$. (Elhadj & Sprott¹²).

Figure 5. Period 6 attracting orbit of the map (2) for $a = 4.0$ and $b = 0.9$ (Elhadj & Sprott¹²). The six points on the graph are magnified.

several fields linked to chaotic dynamical systems are confident in the numerical solutions they found using popular softwares and publish without checking carefully the reliability of their results. Most of the time they compute only few iterates (i.e. few means less than 10^9) of mapping and falsely conclude the existence of chaotic regimes upon these numerical clues.

3.2. *Enigmatic computations for the logistic map (1838)*

In 1838 the belgium mathematician Pierre François Verhulst¹³ introduced a differential equation modelling the grow of population in a simple demographic model, as an improvement of the Malthusian growth model, in which some resistance to the natural increase of population is added.

$$\begin{cases} \frac{dp}{dt} = mp - np^2 \\ p(0) = p_0 \end{cases} \quad (3)$$

the function $p(t)$ being the size of the population of the mankind. He latter, in 1845¹⁴, called logistic function the solution of this equation. Putting

$$x(t) = \frac{n}{m}p(t) \quad (4)$$

Eq. 3 is equivalent to

$$\frac{dx}{dt} = mx(1-x) \quad (5)$$

In 1973, the biologist Sir R. M. May introduced the nonlinear, discrete time dynamical system

$$x_{n+1} = rx_n(1-x_n) \quad (6)$$

as a model for the fluctuations in the population of fruit flies in a closed container with constant food.¹⁵ Due to the similarity of both equations although one is a continuous dynamical system, and the other a discrete one, he called Eq. 6 logistic equation. The logistic map $f_r : [0, 1] \rightarrow [0, 1]$

$$f_r(x) = rx(1-x) \quad (7)$$

associated to Eq. 6 and generally considered for $r \in [0, 4]$ is often cited as an archetypal example of how complex, chaotic behaviour can arise from very simple non-linear dynamical equations.

This dynamical system which has excellent ergodic properties on the real interval $[0, 1]$ has been extensively studied especially by R. M. May¹⁶, and J. Feigenbaum¹⁷ who introduced what is now called the Feigenbaum's constant

$$\delta = 4.669201609102990671853203820466201617258185577...$$

explaining by a new theory (period doubling bifurcation) the onset of chaos.

For every value of r there exist two fixed points: $x = 0$ which is always unstable and $x = \frac{r-1}{r}$ which is stable for $r \in]1, 3[$ and unstable for $r \in]0, 1[\cup]1, 4[$ (see Fig. 6).

When $r = 4$, the system is chaotic. The set

$$\left\{ \frac{5 - \sqrt{5}}{8}, \frac{5 + \sqrt{5}}{8} \right\} = \{0.3454915028, 0.9045084972\}$$

is the period-2 orbit. In fact there exist infinity of periodic orbits and infinity of periods (furthermore several distinct periodic orbits having the same period can coexist). This dynamical system possesses an invariant measure

$$\mu(x) = \frac{1}{\pi \sqrt{x(1-x)}}$$

(see Fig. 7).

It is quite surprising that a simple quadratic equation can exhibit such complex behaviour. If the logistic equation with $r = 4$ modelled the growth of fruit flies, then their population would exhibit erratic fluctuations from one generation to another.

In the coordinate sytem

$$\begin{cases} X = 2x - 1 \\ Y = 2y - 1 \end{cases} \quad (8)$$

the map of Eq. 7 written in the equivalent form (for $r = 4$)

$$g(X) = 1 - 2X^2 \quad (9)$$

was studied in the interval $[-1, 1]$ by T. S. Ulam and J. von Neumann well before the modern chaos era. They proposed it as a computer random number generator.¹⁸

In order to compute periodic orbits whose period is longer than 2 the use of computer is required, as it is equivalent to find roots of polynomial equation of degree greater than 4, for which Galois theory teaches that no closed formula is available. However, numerical computation on computer uses ordinarily double precision numbers (IEEE-754) so that the working interval contains roughly 10^{16} representable points. Doing such a computation¹⁹ in Eq. 6 with $r = 4$ with 1,000 randomly chosen initial guesses, 596, *i.e.*, the majority, converge to the unstable fixed point $x = 0$, and 404 converge to a cycle of period 15,784,521 (see Table 1a).

In an experimental work,²⁰ O. E. Lanford III, does the same search of numerical periodic solution of the logistic equation under the form of Eq. 9. The precise discretization studied is obtained exploiting evenness of this equation to fold the interval $[-1, 0]$ to $[0, 1]$, *i.e.* replacing Eq. 9 by

$$G(X) = |1 - 2X^2| \quad (10)$$

on $[0, 1]$. It is not difficult to see that the folded mapping has the same set of periods as the original one. In order to avoid the particular discretization of this interval when the standard IEEE-754 is used for double precision numbers, the

Table 1a. Coexisting periodic orbits with 1,000 initial guesses

Period	Orbit	Relative Basin Size
1	$\{0\}$ (unstable fixed point)	596 over 1,000
15,784,521	Scattered over the interval	404 over 1,000

Table 1b. Coexisting periodic orbits with 1,000 initial guesses

Period	Orbit	Relative Basin Size
1	$\{0\}$ (unstable fixed point)	890 over 1,000
1,107,319	Scattered over the interval	2 over 1,000
3,490,273	Scattered over the interval	108 over 1,000

working interval is then shifted from $[0, 1]$ to $[1, 2]$ by translation, and the iteration of the translated folded map is programmed in straightforward way. Out of 1,000 randomly chosen initial points, 890, *i.e.*, the overwhelming majority, converged to the fixed point corresponding to the unstable fixed point $x = -1$ in the original representation of Eq. 9, 108 converged to a cycle of period 3,490,273, the remaining 2 converged to a cycle of period 1,107,319 (see Table 1b).

Thus, in both cases at least, the very long-term behaviour of numerical orbits is, for a substantial fraction of initial points, in flagrant disagreement with the true behaviour of typical orbits of the original smooth logistic map.

In others numerical experiments we have performed,^{21,22} the computer working with fixed finite precision is able to represent finitely many points in the interval in question. It is probably good, for purposes of orientation, to think of the case where the representable points are uniformly spaced in the interval. The true logistic map is then approximated by a discretized map, sending the finite set of representable points in the interval to itself.

Describing the discretized mapping exactly is usually complicated, but it is roughly the mapping obtained by applying the exact smooth mapping to each of the discrete representable points and “rounding” the result to the nearest representable point. In our experiments, uniformly spaced points in the interval with several order of discretization (ranging from 9 to 2,001 points) are involved. In each experiment the questions addressed are:

- how many periodic cycles are there, and what are their periods ?
- how large are their respective basins of attraction, *i.e.*, for each periodic cycle, how many initial points give orbits with eventually land on the cycle in question ?

Table 2 shows coexisting periodic orbits for the discretization with regular meshes of $N = 9, 10$ and 11 points. There are respectively 3, 2 and 2 cycles. Table 3 displays cases $N = 99, 100$ and 101 points, there are exactly 2, 4 and 3 cycles. Table 4 stands for regular meshes of $N = 1999, N = 2000$ and $N = 2001$

Figure 6. Cobweb diagram of the logistic map $f_4(x)$.

points.

It seems that the computation of numerical approximations of the periodic orbits leads to unpredictable and somewhat enigmatic results. As says O. E. Lanford III,²⁰ “The reason is that because of the expansivity of the mapping the growth of roundoff error normally means that the computed orbit will remain near the true orbit with the chosen initial condition only for a relatively small number of steps typically of the order of the number of bits of precision with which the calculation is done. It is true that the above mapping like many ‘chaotic’ mappings satisfies a *shadowing theorem* (see Sec. 4.3 in this article) which ensures that the computed orbit stays near to some true orbit over arbitrarily large numbers of steps. The flaw in this idea as an explanation of the behavior of computed orbits is that the shadowing theorem says that the computed orbit approximates *some* true orbit but not necessarily that it approximates a *typical* one.”

He adds, “This suggests the discouraging possibility that this problem may be as hard of that of non equilibrium statistical mechanics”

The existence of very short periodic orbit (Tables 1a, 1b), the existence of a non constant invariant measure (Fig. 7) and the easily recognized shape of the function in the phase space avoid the use of the logistic map as a Pseudo Random Number Generator. However, its very simple implementation in computer program led some authors to use it as a base of cryptosystem.^{23,24}

Figure 7. Invariant measure $\mu(x) = \frac{1}{\pi\sqrt{x(1-x)}}$ of the logistic map $f_4(x)$.

Table 2. Computation on regular meshes of N points

N	Period	Orbit	Basin Size
9	1	{0}	3 over 9
9	1	{6}	2 over 9
9	1	{3, 7}	4 over 9
10	1	{0}	2 over 10
10	2	{3, 8}	8 over 11
11	1	{0}	3 over 11
11	4	{3, 8, 6, 9}	8 over 11

3.3. Collapsing orbit of the symmetric tent map

Another often studied discrete dynamical system is defined by the symmetric tent map on the interval $J = [-1, 1]$

$$x_{n+1} = T_a(x_n) \quad (11)$$

$$T_a(x) = 1 - a|x| \quad (12)$$

Despite its simple shape (see Fig. 8), it has several interesting properties. First, when the parameter value $a = 2$, the system possesses chaotic orbits. Because of its piecewise-linear structure, it is easy to find those orbits explicitly. More, owing to its simple definition, the symmetric tent map's shape under iteration is very well

Table 3. Computation on regular meshes of 99, 100 and 101 points

N	Period	Orbit	Basin Size
99	1	$\{0\}$	3 over 99
99	10	$\{3, 11, 39, 93, 18, 58, 94, 15, 50, 97\}$	96 over 99
100	1	$\{0\}$	2 over 100
100	1	$\{74\}$	2 over 100
100	6	$\{11, 39, 94, 18, 58, 96\}$	72 over 100
100	7	$\{7, 26, 76, 70, 82, 56, 97\}$	24 over 100
101	1	$\{0\}$	3 over 101
101	1	$\{75\}$	2 over 101
101	1	$\{19, 61, 95\}$	96 over 101

Table 4. Computation on regular meshes of 1,999, 2,000 and 2,001 points

N	Period	Orbit	Basin Size
1999	1	$\{0\}$	3 over 1999
1999	4	$\{554, 1601, 1272, 1848\}$	990 over 1999
1999	8	$\{3, 11, 43, 168, 615, 1702, 1008, 1997\}$	1006 over 1999
2000	1	$\{0\}$	2 over 2000
2000	1	$\{1499\}$	14 over 2000
2000	2	$\{691, 1808\}$	138 over 2000
2000	3	$\{376, 1221, 1900\}$	6 over 2000
2000	8	$\{3, 11, 43, 168, 615, 1703, 1008, 1998\}$	1840 over 2000
2001	1	$\{0\}$	5 over 2001
2001	1	$\{1500\}$	34 over 2001
2001	2	$\{691, 1809\}$	92 over 2001
2001	8	$\{3, 11, 43, 168, 615, 1703, 1011, 1999\}$	608 over 2001
2001	18	$\{35, 137, 510, 1519, 1461, 1574, \dots\}$	263 over 2001
2001	25	$\{27, 106, 401, 1282, 1840, 588, \dots\}$	1262 over 2001

understood. The invariant measure is the Lebesgue measure. Finally, and perhaps the most important, the tent map is conjugate to the logistic map, which in turn is conjugate to the Hénon map (see Sec. 4.1) for small values of b .²⁵

However the symmetric tent map is dramatically numerically unstable: Sharkovskii's theorem applies for it.²⁶ When $a = 2$ there exists a period three orbit, which implies that there is infinity of periodic orbits. Nevertheless the orbit of almost every point of the interval J of the discretized tent map eventually wind up to the (unstable) fixed point $x = -1$ (this is due to the binary structure of floating points) and there is no numerical attracting periodic orbit.²⁷

The numerical behaviour of iterates with respect to chaos is worse than the numerical behaviour of iterates of the approximated logistic map. This is why the tent map is never used to generate numerically chaotic numbers.

Figure 8. Tent map $T_2(x)$.

3.4. statistical properties

Many others examples could be given, but those given may serve to illustrate the intriguing character of the results, the outcomes proves to be extremely sensitive to the details of the experiment, but the findings all have a similar flavour: a relatively small number of cycles attract near all orbits, and the lengths of these significant cycles are much larger than one but much smaller than the number of representable points. P. Diamond and al.^{28,29}, suggest that statistical properties of the phenomenon of computational collapse of discretized chaotic mapping can be modelled by random mappings with an absorbing centre. The model gives results which are very much in line with computational experiments and there appears to be a type of universality summarised by an *Arcsin* law. The effects are discussed with special reference to the family of dynamical systems

$$x_{n+1} = 1 - |1 - 2x_n|^l, \quad 0 \leq x \leq 1, \quad 1 \leq l \leq 2 \quad (13)$$

Computer experiments show close agreement with prediction of the model. However these results are of statistical nature, they do not give accurate information on the exact nature of the periodic orbits (*e.g.* length of the shortest or the greatest one, size of their basin of attraction ...). Following this work, G. Yuan and J. A. Yorke³⁰ study precisely the collapse to the repelling fixed point $x = -1$ of the iterates of the one dimensional dynamical system

$$x_{n+1} = 1 - 2|x_n|^l, \quad -1 \leq x \leq 1, \quad l > 2 \quad (14)$$

for a large fraction of initial conditions when calculated on a mesh of N points

equally spaced from -1 to $+1$ (as we have done in Sec. 3.2). The map associated to this system

$$T_{a,l}(x) = 1 - a|x|^l$$

being an usual nonlinear generalization of the map $T_a(x)$ of Eq. 12. They not only prove rigorously that the collapsing effect does not vanish when arbitrarily high numerical precision is employed, but also they give a lower bound of the probability for which it happens. They define $P_{collapse}$ which is the probability that there exists n such that $x_n = -1$ and they give the proof that $P_{collapse}$ depends only on the numbers N and l . The lower bound of $P_{collapse}$ is given by

$$\liminf_{N \rightarrow \infty} P_{collapse} \geq \sqrt{\pi} K' [1 - \operatorname{erf}(K')] \exp(K')^2 > 0 \quad (15)$$

$$K' = lK^{-1} 2^{-1/.2-1/l} \left[1 + \left((2l)^{1/l} - 1 \right)^{-2} \right]^{-1/2}$$

$$K = \left(\sum_{i=1}^{\infty} k_i^2 \right)^{1/2}$$

$$k_i = l \left[(i + 1/2)^{1/l} - (i - 1/2)^{1/l} \right]$$

with

$$\operatorname{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt \quad (16)$$

They plot the curve given by Eq. 15 along with the numerical results (Figure 9). Each numerical datum is obtained as follows. For each l they sample 10,000 pairs of (\bar{l}, x) from $(l - 0.01l, l + 0.01l) \times (-1, 1)$ with uniform distribution. For each sample they keep iterating the dynamical system defined by Eq. 14 with the initial condition x until the numerical trajectory repeats. Then they calculate the portion of trajectories that eventually map to -1 . The deviation is clear since Eq. 15 only gives a lower bound. Nonetheless the theoretical curve reveals the fact that $P_{collapse}$ is already substantial for $l = 3$ and it predicts that $P_{collapse}$ increases as l increases and that $\lim_{l \rightarrow \infty} P_{collapse} = 1$.

4. Shadowing and parameter-shifted shadowing property of mappings of the plane

4.1. Hénon map (1976) found by mistake

The chaotic behavior of mapping of the real line is relatively simple compared to the behavior of mapping on the plane. These mappings could be seen as a simple expansion in a phase space with increased dimension of both models (logistic and tent) we have introduced in the previous section. However they have been discovered not in this “ascending” way, instead they come in “descending way” as metaphor of Poincaré map of 3-D continuous dynamical systems.

Figure 9. $P_{collapse}$ as a function of l . The curve in this figure is the lower bound computed from Eq. 15. Numerical results are obtained by using different numerical precisions are also shown in this figure "+" -double precision "o" -single precision "x"-fixed precision 10^{-12} (from ³⁰).

Figure 10. Observatory of Nice, the office of Michel Hénon was located inside the building.

In order to study numerically the properties of the Lorenz attractor¹, M. Hénon an astronomer of the observatory of Nice, France (see Fig. 10) introduced in 1976⁵ a simplified model of the Poincaré map of this attractor. The Lorenz attractor being in dimension 3, the corresponding Poincaré map is a map from the plane \mathbb{R}^2 to \mathbb{R}^2 . The Hénon map is then also defined in dimension 2 as

$$H_{a,b} : \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} y + 1 - ax^2 \\ bx \end{pmatrix} \quad (17)$$

It is associated to the dynamical system

$$\begin{cases} x_{n+1} = y_n + 1 - ax_n^2 \\ y_{n+1} = bx_n \end{cases} \quad (18)$$

For the parameter value $a = 1.4$, $b = 0.3$, M. Hénon pointed out numerically that there exists an attractor with fractal structure. This was the first example of strange attractor (previously introduced by D. Ruelle and F. Takens³¹) for a mapping defined by an analytic formula.

As highlighted in the sequence of Figs. 11-14, the like-Cantor set structure in one direction orthogonal to the invariant manifold in this simple mapping was a dramatic surprise in the community of physicists and mathematicians.

Nowadays hundreds of research papers have been published on this prototypical map in order to fully understand its innermost structure. However as for 1-dimensional dynamical systems, there is a discrepancy between the mathematical properties of this map in the plane and the numerical computations done using (IEEE-754) double precision numbers.

If we call Megaperiodic orbits,⁶ those whose length of the period belongs to the interval of natural numbers $[10^6, 10^9[$ and Gigaperiodic orbits, those whose length of the period belongs to the interval $[10^6, 10^9[$, Hénon map possesses both Mega and Gigaperiodic orbits. On a Dell computer with a Pentium IV microprocessor running at 1.5 Gigahertz frequency, using a Borland C compiler and computing with ordinary (IEEE-754) double precision numbers, one can find for $a = 1.4$ and $b = 0.3$ one attracting period of length 3,800,716,788, *i.e.* two hundred forty times longer than the longest period of the one-dimensional logistic map (Table 1a). This periodic orbit (we call it here Orbit 1) is numerically slowly attracting. Starting with the initial value

$$(x_0, y_0)_1 = (-0.35766, 0.14722356)$$

one winds up:

$$\begin{aligned} (x_{11,574,730,767}, y_{11,574,730,767})_1 &= (x_{15,375,447,555}, y_{15,375,447,555})_1 \\ &= (1.27297361350955662, -0.0115735710153616837) \end{aligned}$$

The length of this period is obtained subtracting

$$15,375,447,555 - 11,574,730,767 = 3,800,716,788$$

However this Gigaperiodic orbit is not unique: starting with the other initial value

$$(x_0, y_0)_2 = (0.4725166, 0.25112222222356)$$

the following Megaperiodic orbit (Orbit 2) of period 310,946,608 is computed

$$\begin{aligned}(x_{12,935,492,515}, y_{12,935,492,515})_2 &= (x_{13,246,439,123}, y_{13,246,439,123})_2 \\ &= (1.27297361350865113, -0.0115734779561870744)\end{aligned}$$

Remark 4.1. This second orbit can be reached more rapidly starting from the other initial value

$$(x_0, y_0) = (0.881877775591, 0.0000322222356)$$

then

$$(x_{4,459,790,707}, y_{4,459,790,707}) = (1.27297361350865113, -0.0115734779561870744)$$

Remark 4.2. It is possible that some others periodic orbits coexist with both Orbit 1 and Orbit 2. However there is no peculiar method but the brute force to find it if any.

Remark 4.3. The comparison between Orbit 1 and Orbit 2 gives a perfect idea of the sensitive dependence on initial conditions of chaotic attractors:

Orbit 1 passes through the point

$$(1.27297361350955662, -0.0115735710153616837)$$

and Orbit 2 passes through the point

$$(1.27297361350865113, -0.0115734779561870744)$$

The same digits of the coordinates of these points are bold printed, they are very close.

The discovery of a strange attractor for maps of the plane boosted drastically the research on chaos in the years 70'. This is miraculous considering that if M. Hénon tried to test rigorously his model nowadays with powerful computers he should only found long periodic orbits. In 1976, M. Hénon used the electronic pocket calculator built by Hewlett-Packard company HP-65 (Fig. 15) and one of the only two computers available at the university of Nice a IBM 7040 (Fig.16), the other one was a IBM 1130, slower. The HP-65 first introduced in 1974 was worth 750 € (equivalent to 3,500 € nowadays), the IBM 7040, was worth 1,100,000 € (equivalent to 7,800,000 € in the year 2012).

He concluded,⁵ "The simple mapping (4) (*i.e.* Eq. 17 in this article) appears to have the same basic properties as the Lorenz system. Its numerical exploration is much simpler: in fact most of the exploratory work for the present paper was carried out with a programmable pocket computer (HP-65). For the more extensive computations of Figures 2 to 6, we used a IBM 7040 computer, with 16-digit accuracy. The solutions can be followed over a much longer time than in the case of a system of differential equations. The accuracy is also increased since there are no integration errors. Lorenz (1963) inferred the Cantor-set structure of the attractor

Figure 11. Hénon strange attractor, 10000 successive points obtained by iteration of the mapping.

from reasoning, but could not observe it directly because the contracting ratio after one ‘circuit’ was too small: 7×10^{-5} . A similar experience was reported by Pomeau (1976). In the present mapping, the contracting ratio after one iteration is 0.3, and one can easily observe a number of successive levels in the hierarchy. This is also facilitated by the larger number of points. Finally, for mathematical studies the mapping (4) might also be easier to handle than a system of differential equations.”

The large number of points was in fact very few⁵: “The transversal structure (across the curves) appears to be entirely different, and much more complex. Already on Figures 2 and 3 (*i.e. Fig. 11 in this article*) a number of curves can be seen, and the visible thickness of some of them suggests that they have in fact an underlying structure. Figure 4 (*i.e. Fig. 12 in this article*) is a magnified view of the small square of Figure 3: some of the previous ‘curves’ are indeed resolved now into two or more components. The number n of iterations has been increased to 10^5 , in order to have a sufficient number of points in the small region examined. The small square in Figure 4 is again magnified to produce Figure 5 (*i.e. Fig. 13 in this article*), with n increased to 10^6 : again the number of visible ‘curves’ increases. One more enlargement results in Fig. 6 (*i.e. Fig. 14 in this article*), with $n = 5 \times 10^6$: the points become sparse but new curves can still easily be traced.”

In 1976, the one million €, IBM 7040 took several hours to compute five millions points, today a basic three hundred euros laptop, runs the same computation in one hundredth of a second.

With so few iterations nowadays the following claim⁵: “These figures strongly suggest that the process of multiplication of ‘curves’ will continue indefinitely, and

Figure 12. Enlargement of the squared region of Figure 11. The number of computed points is increased to $n = 10^5$.

that each apparent ‘curves’ is in fact made of an infinity of quasi-parallel curves. Moreover, Figures 4 to 6 indicate the existence of a hierarchical sequence of ‘levels’, the structure being practically identical at each level save for a scale factor. This is exactly the structure of a Cantor set.” should be obviously untrue. One can assert that Hénon map was found not by chance (the reasoning of M. Hénon was straightforward) but by mistake. It is a great luck for the expand of chaos studies!

4.2. Lozi map (1977) a tractable model

Using one of the first desktop electronic calculator HP-9820, he usually employed for initiate to computer sciences, mathematics teacher trainees, R. Lozi found out, on june 15, 1977, (on the scientific campus of the university of Nice, few kilometers apart of the observatory of this town of the French Riviera where M. Hénon worked), that the linearized version of the Hénon map displayed numerically the same structure of strange attractors, but the curves were replaced by straight lines. He published this result in the proceedings of a conference on dynamical systems which held in Nice in july of the same year,³² in a very short paper of one and an half pages.

The aim of R. Lozi, a numerical analyst, was to allow algebraic computations on an analog of the Hénon map, such direct computation being untractable on the original model due to the square function. He changed this function with a absolute value, defining the map

Figure 13. Enlargement of the squared region of Figure 12, $n = 10^6$.

Figure 14. Enlargement of the squared region of Figure 13, $n = 5 \times 10^6$.

$$L_{a,b} : \begin{pmatrix} x \\ y \end{pmatrix} = \begin{pmatrix} y + 1 - a|x| \\ bx \end{pmatrix} \quad (19)$$

Figure 15. Electronic pocket calculator HP-65.

Figure 16. Computer IBM 7040.

and the associate dynamical system

$$\begin{cases} x_{n+1} = y_n + 1 - a|x_n| \\ y_{n+1} = bx_n \end{cases} \quad (20)$$

Figure 17. Lozi map $L_{1.7,0.5}$.

He then found out on the plotter device attached to his small primitive computer that for the value $a = 1.7$, $b = 0.5$, the same Cantor-set like structure was apparent. Due to the linearity of this new model, it is possible to compute explicitly any periodic orbit solving a linear system. Moreover in december 1979, M. Misiurewicz² gave a talk in the famous conference organized in december 1979 at New-York by the New-York academy of science in which he established rigorously the proof that what he call “Lozi map” has a strange attractor for some parameter values (including the genuine one $a = 1.7$, $b = 0.5$). Since that time, hundreds of papers have been published on the topic.

Remark 4.4. The open set \mathcal{M} of the parameter space (a, b) where the existence of strange attractor is proved is now called the *Misiurewicz domain*. It is defined as

$$0 < b < 1, a > b + 1, 2a + b < 4, a\sqrt{2} > b + 2, b < \frac{(a^2 - 1)}{(2a + 1)} \quad (21)$$

Today, in the same conditions of computation as for Hénon map (see Sec. 4.1), running the computation during nineteen hours, one can find a Gigaperiodic attracting orbit of period 436, 170, 188, 959 more than one hundred times longer than the period of Orbit 1 found for the Hénon map.

Starting with

$$(x_0, y_0) = (0.88187777591, 0.0000322222356)$$

one obtains

$$\begin{aligned}
(x_{686,295,403,186}, y_{686,295,403,186}) &= (x_{250,125,214,227}, y_{250,125,214,227}) \\
&= (1.343484444450739479, -2.07670041497986548 \cdot 10^{-7})
\end{aligned}$$

There is a transient regime before the orbit is reached. It seems that there is no periodic orbit with a smaller length. This could be due to the quasihyperbolic nature of the attractor. However, the parameter-shifted shadowing property, the orbit-shifted shadowing property of Lozi map (and generalized Lozi map), which are new variations of the shadowing property which ensures that pseudo-orbits of a homeomorphism can be traceable by actual orbits even if rounding errors in computing are not inevitable, has been recently proved.^{7,33}

4.3. *Shadowing, parameter-shifted shadowing and orbit-shifted shadowing properties*

The shadowing property is the property which ensures that pseudo-orbits (i.e. orbits computed numerically using finite precision number) of a homeomorphism can be traceable by actual orbit. The concept and primary results of shadowing property for uniformly hyperbolic diffeomorphisms were introduced by D. V. Anosov³⁴ and R. Bowen,³⁵ who proved that such diffeomorphisms have the shadowing property. Various papers associated with shadowing property and uniform hyperbolicity were presented by many authors. Comprehensive expositions on these works were included in books by K. Palmer³⁶ or S. Y. Pilyugin.³⁷

The precise definition of this property is³⁸

Definition 4.1. (*Shadowing*) Let (X, d) a metric space, $f : X \rightarrow X$ a function and let $\delta > 0$. A sequence $\{x_k\}_{k=p}^q$, $(p, q) \in \mathbb{N}^2$ of points is called a δ -pseudo-orbit of f if $d(f(x_k), x_{k+1}) < \delta$ for $p \leq k \leq q-1$ (e.g. a numerically computed orbit is a pseudo-orbit). Given $\epsilon > 0$, the pseudo-orbit $\{x_k\}_{k=p}^q$ is said ϵ -shadowed by $x \in X$, if $d(f^k(x), x_k) < \epsilon$ for $p \leq k \leq q$. One says that f has the *shadowing property* if for $\epsilon > 0$ there is $\delta > 0$ such that every δ -pseudo-orbit of f can be ϵ -shadowed by some point.

However, if one relaxes the uniform hyperbolicity condition on diffeomorphisms slightly (Lozi map, for example, has not such a property), then many problems concerning the shadowing property are not solved yet. Nowadays, it is widely supposed that many diffeomorphisms producing chaos **would not have the shadowing property**. In fact, Yuan and Yorke³⁹ found an open set of absolutely nonshadowable C^1 maps for which nontrivial attractors supported by partial hyperbolicity include at least two hyperbolic periodic orbits whose unstable manifolds have different dimensions. Moreover, Abdenur and Díaz⁴⁰ showed recently that the shadowing property does not hold for diffeomorphisms in an open and dense subset of the set of C^1 -robustly nonhyperbolic transitive diffeomorphisms.

In order to fix this issue the notion of the parameter-shifted shadowing property (for short *PSSP*) was introduced by E. M. Coven, I. Kan and J. A. Yorke.⁴¹ In fact, they proved that the tent map (Eq. 12) has the parameter-fixed shadowing property for almost every sloop a in the open interval $I = (\sqrt{2}, 2)$, but do not have it for any a in a certain dense subset of I . Moreover, they proved that, for any $a \in I$, the tent map T_a has *PSSP*. The definition of this variant property being³³

Definition 4.2. (*PSSP*) Let $\{f_a\}_{a \in J}$ be a set of maps on \mathbb{R}^2 where J is an open interval in \mathbb{R} .

- For $\delta > 0$, the sequence $\{x_n\}_{n \geq 0} \subset \mathbb{R}^2$ is called δ -pseudo-orbit of f_a if $\|f_a(\mathbf{x}_n) - \mathbf{x}_{n+1}\| \leq \delta$ for any integer $n \geq 0$.
- For $a \in J$, we say that f_a has the *parameter-shifted shadowing property* if, for any $\epsilon > 0$, there exist $\delta = \delta(a, \epsilon) > 0$, $\tilde{a} = \tilde{a}(a, \epsilon) \in J$ such that any δ -pseudo-orbit $\{\mathbf{x}_n\}_{n \geq 0}$ of f_a can be ϵ -shadowed by an actual orbit of $f_{\tilde{a}}$, that is, there exists a $\mathbf{y} \in \mathbb{R}^2$ such that $\|f_{\tilde{a}}^n(\mathbf{y}) - \mathbf{x}_{n+1}\| \leq \epsilon$ for any $n \geq 0$.

For Lozi map, S. Kiriki and T. Soma proof that³³

Theorem 4.1. *There exists a nonempty open set \mathcal{O} of the Misiurewicz domain \mathcal{M} such that, for any $(a, b) \in \mathcal{O}$, the Lozi map $L_{a,b}$ has the parameter-shifted shadowing property in a one-parameter family $\{L_{\tilde{a},b}\}_{\tilde{a} \in J}$ fixing b , where J is a small open interval containing a .*

However they note that “The problem of parameter-fixed shadowability is still open even for the Lozi family as well as the Hénon family.”

Another variation of shadowability is the orbit-shifted shadowing property (for short *OSSP*) recently introduced by A. Sakurai⁷ in order to study generalized Lozi maps introduced by L.-S. Young.⁴² The limited extend of this article does not allow us to recall the complex definition of these generalized maps.

Definition 4.3. For $\delta_0 > 0$, $\delta_1 > 0$, and $\delta > 0$, with $\delta_0 \leq \eta_0$, a sequence $\{\mathbf{x}_n\}_{n \geq 0}$ in $R = [0, 1] \times [0, 1]$ is an (δ_0, δ_1) -shifted δ -pseudo-orbit of f if, for any $n \geq 1$, \mathbf{x}_n and \mathbf{x}_{n+1} satisfy the following conditions.

- $\|f(\mathbf{x}_n) - \mathbf{x}_{n+1}\| \leq \delta$ if $B_{\delta_0}(\mathbf{x}_{n-1}) \cap (S_1 \cup S_2) = \emptyset$.
- $\|f(\mathbf{x}_n) - (\delta_1, 0) - \mathbf{x}_{n+1}\| \leq \delta$ if $B_{\delta_0}(\mathbf{x}_{n-1}) \cap S_1 \neq \emptyset$.
- $\|f(\mathbf{x}_n) + (\delta_1, 0) - \mathbf{x}_{n+1}\| \leq \delta$ if $B_{\delta_0}(\mathbf{x}_{n-1}) \cap S_2 \neq \emptyset$.

where S_1 and S_2 are the two components of the essential singularity set of f .

Definition 4.4. (*OSSP*) We say that f has the orbit-shifted shadowing property if, for any $\epsilon > 0$ with $\epsilon \leq \eta_0$, there exist $\delta_0, \delta_1, \delta > 0$ such that any (δ_0, δ_1) -shifted δ -pseudo-orbit $\{\mathbf{x}_n\}_{n \geq 0}$ in R of f can be ϵ -shadowed by an actual orbit of f , that is, there exists $\mathbf{z} \in R$ such that $\|f^n(\mathbf{z}) - \mathbf{x}_n\| \leq \epsilon$ for any $n \geq 0$.

Theorem 4.2. *Any generalized Lozi map f satisfying the conditions (2.1)–(2.4) given in⁷ has the orbit-shifted shadowing property. More precisely, for any $0 <$*

$\epsilon \leq \eta_0$, there exists $\delta > 0$ such that any $(\epsilon, \epsilon/2)$ -shifted δ -pseudo-orbit of f in R is ϵ -shadowed by an actual orbit.

For sake of simplicity, we do not give the technical conditions (2.1)-(2.4), however one can proof that any original Lozi maps $L_{a,b}$ indicated in Theorem 4.1 satisfies these conditions.

In conclusion to both Secs. 3 and 4, it appears that if, owing to the introduction of computers since forty years, it is easy to compute orbits of mapping in 1 or 2-dimension (and more generally in finite dimension), it is not unproblematic to obtain reliable results. The mathematical study of what is actually computed (for the orbits) is a rather difficult and still challenging problem. Trusty results are obtained under rather technical assumptions. Considering a new mathematical tool, the Global Orbit Pattern (*GOP*) of a mapping on finite set, R. Lozi and C. Fiol^{19,21} obtain some combinatorial results in 1-dimension.

There is not place in this paper to consider other computations than the computations of orbits. However there is a need for several others reliable numerical results as the Lyapunov numbers,⁴³ the fractal dimensions (correlation, capacity, Hausdorff,...) and Lyapunov spectrum,⁴⁴ topological entropy,⁴⁵ extreme value laws.^{46,47} ...The researches are very active in these fields. One can mention as an example the relationship between the expected value of the period scales and the correlation dimension for the case of fractal chaotic attractors of D-dimensional maps.⁴⁸

Theorem 4.3. *The expected value of the period scales with round off ϵ is*

$$\overline{m} = \epsilon^{-D/2} \quad (22)$$

where D is the correlation dimension of the chaotic attractor. The periods m have substantial statistical fluctuation. That is, $P(m)$, the probability that the period is m , is not strongly peaked around \overline{m} . This probability is given by

$$P(m) = \left(\frac{1}{\overline{m}}\right) F\left(\frac{\sqrt{\frac{\pi}{8m}}}{\overline{m}}\right) \quad (23)$$

where

$$F(x) = \sqrt{\frac{\pi}{8}} \left[1 - \sqrt{\frac{\pi}{2}} \operatorname{erf}\left(\frac{x}{\sqrt{2}}\right) \right] \quad (24)$$

and $\operatorname{erf}(x)$ is defined by Eq.16

5. Continuous models

We have highlighted the close relationship between continuous and discrete models via Poincaré map. We have also pointed out that M. Hénon constructed his model in order to compute more easily Poincaré map of the Lorenz model which is crunching too fast for direct numerical computations. It is time to study directly these initial equations together with the metaphors ones which that follows naturally: the Rössler and the Chua equations.

5.1. Lorenz attractor (1963)

The following non linear system of differential equations was introduced by E. Lorenz^a in 1963.¹ As a crude model of atmospheric dynamics, these equations led Lorenz to the discovery of sensitive dependence of initial conditions - an essential factor of unpredictability in many systems (*e. g.* meteorology).

$$\begin{cases} \dot{x} = -\sigma(x + y) \\ \dot{y} = \rho x - y - xz \\ \dot{z} = xy - \beta z \end{cases} \quad (25)$$

Numerical simulations for an open neighbourhood of the classical parameter values

$$\sigma = 10, \rho = 28, \beta = \frac{8}{3} \quad (26)$$

suggest that almost all points in phase space tend to a strange attractor the *Lorenz attractor*. One can note that the system is invariant under the transformation

$$S(x, y, z) = (-x, -y, -z) \quad (27)$$

This means that any trajectory that is not itself invariant under S must have a symmetric “twin trajectory.” For $\rho > 1$ there are three fixed points: the origin and the two “twin points”

$$C^{\pm} = \left(\pm \sqrt{\beta(\alpha - 1)}, \pm \sqrt{\beta(\alpha - 1)}, \rho - 1 \right)$$

For the parameter values generally considered, C^{\pm} have a pair of complex eigenvalues with positive real part, and one real, negative eigenvalue. The origin is a saddle point with two negative and one positive eigenvalue satisfying

$$0 < -\lambda_3 < -\lambda_2 < \lambda_1 < -\lambda_1$$

Thus the stable manifold of the origin $W^s(0)$ is two dimensional and the unstable manifold of the origin $W^u(0)$ is one dimensional. As indicated by M. Hénon⁵ in his initial publication the flow contracts volumes at a significant rate (see Sec. 4.1). As the divergence of the vector field is $-(\sigma + \beta + 1)$ the volume of a solid at time t can be expressed as

$$V(t) = V(0)e^{-(\sigma+\beta+1)t} \approx V(0)e^{-13.7t}$$

^aEdward Lorenz, born on May, 23, 1917 at west Hartford (Connecticut), dead on April, 16, 2008 at Cambridge (Massachusset), studied the Rayleigh-Bénard problem (*i. e.* the motion of a flow heated from below, as an approach of the atmospheric turbulence) using a primitive Royal McBee LPG-30 computer. He first considered series of 12 differential equations when he discovered the “butterfly effect”. Then he simplified his model from 12 to only three equations. As for Hénon model, his discovery was made by mistake due to rounding errors.

Figure 18. Lorenz attractor.

for the classical parameter values. This means that the flow contracts volumes almost by a factor *one million* per time unit which is quite extreme. There appears to exist a forward invariant open set U containing the origin but bounded away from C^\pm . The set U is a double torus (one with two holes), with its holes centered around the two excluded fixed points. If one lets φ denote the flow of Eq. 25, there exists the maximal invariant set

$$\mathcal{A} = \bigcap_{t \geq 0} \varphi(U, t)$$

Due to the strong dissipativity of the flow, the attracting set \mathcal{A} must have zero volume. As indicated by W. Tucker⁴⁹, it must also contain the unstable manifold $W^u(0)$ of the origin, which seems to spiral around C^\pm in a very complicated non periodic fashion (see Fig. 18).

In particular \mathcal{A} contains the origin itself, and therefore the flow on \mathcal{A} can not have a hyperbolic structure. The reason is that fixed points of the vector field generate discontinuities for the return maps (Poincaré maps), and as a consequence, the hyperbolic splitting is not continuous. Apart from this, the attracting set appears to have a strong hyperbolic structure.

5.2. Geometric Lorenz attractor

As it was very difficult to extract rigorous information about the attracting set \mathcal{A} from the differential equations themselves, M. Hénon constructed his famous model (Sec. 4.1) in order to understand numerically its inner structure. In another way of

research, a *geometric model* of the Lorenz flow was introduced by J. Guckenheimer and R. Williams⁵⁰ at the end of the seventies (see Fig. 19). This model has been extensively studied and it is well understood today. The question whether or not the original Lorenz system for such parameter values has the same structure as the geometric Lorenz model has been unsolved for more than 30 years. By combination of normal form theory and rigorous computations, W. Tucker⁵¹ answered this question affirmatively, that is, for classical parameters, the original Lorenz system has a robust strange attractor which is given by the same rules as for the geometric Lorenz model. From these facts, it is known that the geometric Lorenz model is crucial in the study of Lorenz dynamical systems. Oddly enough the original equations introduced by Lorenz have remained a puzzle until the same author proved in 1999 in his Ph.D Thesis⁴⁹ the following theorem

Theorem 5.1. *For the classical parameter values, the Lorenz equations support a robust strange attractor \mathcal{A} . Furthermore the flow admits a unique SRB measure μ_X with $\text{supp}(\mu_X) = \mathcal{A}$.*

Remark 5.1. SRB measures, are an invariant measures introduced by Ya. Sinai, D. Ruelle and R. Bowen in the 1970's. These objects play an important role in the ergodic theory of dissipative dynamical systems with chaotic behavior. Roughly speaking, SRB measures are the invariant measures most compatible with volume when volume is not preserved. They provide a mechanism for explaining how local instability on attractors can produce coherent statistics for orbits starting from large sets in the basin.

In addition, W. Tucker indicates, “In fact, we prove that the attracting set is a singular hyperbolic attractor. Almost all nearby points separate exponentially fast until they end up on opposite sides of the attractor. This means that a tiny blob of initial values soon smears out over the entire attractor. It is perhaps worth pointing out that the Lorenz attractor does not act quite as the geometric model predicts. The latter can be reduced to an interval map which is everywhere expanding. This is not the case for the Lorenz attractor: there are large regions in the attracting set that are contracted in all directions under the return map. However, such regions only require a few more iterations before accumulating expansion. This corresponds to the interval map being eventually expanding, and does not lead to any different qualitative long time behaviour. Apart from this, the Lorenz attractor is just as the geometric model predicts: it contains the origin, and thus has a very complicated Cantor book structure.”

One of the many ingredients required for the proof of this theorem is a rigorous arithmetics on a trapping region consisting in 350 adjacent rectangles belonging to the return plate $z = 27 = \rho - 1$. W. Tucker says “One major advantage of our numerical method is that we totally eliminate the problem of having to control the global effects of rounding errors due to the computer's internal floating point representation. This is achieved by using a high dimensional analogue of *interval*

Figure 19. Geometric Lorenz model from⁵²

arithmetic. Each object Ξ (e. g. a rectangle or a tangent vector) subjected to computation is equipped with a maximal absolute error Δ_Ξ , and can thus be represented as a box $\Xi \pm \Delta_\Xi = [\Xi_1 - \Delta_{\Xi_1}, \Xi_1 + \Delta_{\Xi_1}] \times \cdots \times [\Xi_n - \Delta_{\Xi_n}, \Xi_n + \Delta_{\Xi_n}]$. When following an object from one intermediate plane to another, we compute upper bounds on the images of $\Xi_i + \Delta_{\Xi_i}$, and lower bounds on the images of $\Xi_i - \Delta_{\Xi_i}$, $i = 1, \dots, n$. This results in a new box $\tilde{\Xi} \pm \Delta_{\tilde{\Xi}}$, which strictly contains the exact image of $\Xi \pm \Delta_\Xi$. To ensure that we have strict inclusion, we use quite rough estimates on the upper and lower bounds. This gives us a margin which is much larger than any error caused by rounding possibly could be. Hence, the rounding errors are taken into account in the computed box $\tilde{\Xi} \pm \Delta_{\tilde{\Xi}}$, and we may continue to the following intermediate plane by restarting the whole process.

As long as we do not flow close to a fixed point, the local return maps are well defined diffeomorphisms, and the computer can handle all calculations. Some rectangles, however, will approach the origin (which is fixed point), and then the computations must be interrupted as discussed in the previous section (*i. e. the normal form theory*)."

The work of W. Tucker is a big step forward reliability of numerical solution of chaotic continuous dynamical system. However it has been obtained after a great deal of effort (he published two revised versions of the proof anytime he detected a mistake in the code) which can not be afforded to any new continuous chaotic model.

Figure 20. Lorenz map from.⁵²

5.3. Lorenz map

In contrast the analysis of the Poincaré map associated to the geometric model of the Lorenz flow allows the use of the parameter-shifted shadowing property.⁵² This first return map on a Poincaré cross section of a geometric Lorenz flow is called a *Lorenz map* $L : \Sigma \setminus \Gamma \rightarrow \Sigma$, where $\Sigma = \{(x, y) \in \mathbb{R}^2; |x|, |y| \leq 1\}$ and $\Gamma = \{(0, y) \in \mathbb{R}^2; |y| \leq 1\}$. More precisely it is defined as follows

Definition 5.1. (*Lorenz map*) Let Σ_{\pm} denote the components of $\Sigma \setminus \Gamma$ with $\Sigma_{\pm} \ni (\pm 1, 0)$ (see Fig. 19). A map $L : \Sigma \setminus \Gamma \rightarrow \Sigma$, is said to be a Lorenz map if it is a piecewise C^1 diffeomorphism which has the form

$$L(x, y) = (\alpha(x), \beta(x, y))$$

where $\alpha : [-1, 1] \setminus \{0\} \rightarrow [-1, 1]$ is a piecewise C^1 -map with symmetric property $\alpha(-x) = -\alpha(x)$ and satisfying

$$\begin{cases} \lim_{x \rightarrow 0^+} \alpha(x) = -1, & \alpha(1) < 1 \\ \lim_{x \rightarrow 0^+} \alpha'(x) = \infty, & \alpha'(x) > \sqrt{2} \text{ for any } x \in (0, 1] \end{cases}$$

(see Fig. 20a), and $\beta : \Sigma \setminus \Gamma \rightarrow [-1, 1]$ is a contraction in the y -direction. Moreover, it is required that the images $L(\Sigma_+)$, $L(\Sigma_-)$ are mutually disjoint cusps in Σ , where the vertices \mathbf{v}_+ , \mathbf{v}_- of $L(\Sigma_+)$ are contained in $\{\mp 1\} \times [-1, 1]$ respectively (see Fig. 20b).

Then, S. Kiriki and T. Soma proved the parameter-shifted shadowing property (*PSSP*) for Lorenz maps.⁵²

Theorem 5.2. *There exists a definite set \mathcal{L} of Lorenz maps satisfying the following condition:*

For any $L \in \mathcal{L}$ and any $\epsilon > 0$, there exist $\mu > 0$ and $\delta > 0$ such that any δ -pseudo orbit of the Lorenz map L_μ with $L_\mu(x, y) = L(x, y) - (\mu x, 0)$ is ϵ -shadowed by an actual orbit of L .

Theorem 5.3. *Any geometric Lorenz flow controlled by a Lorenz map $L \in \mathcal{L}$ has the parameter-shifted shadowing property.*

Due to the lack of space, we refer to⁵² for the strict description of \mathcal{L} .

Besides this work on the Lorenz map, there are many some others rigorous results on Lorenz equations. Z. Galias and P. Zygliczyński,^{53,54} for example, are basing their result on the notion of the topological shifts maps (TS-maps). Let $\Sigma = \{(x, y, z) \in \mathbb{R}^3; z = \rho - 1\}$ which is the standard choice for the Poincaré section. Let \mathbf{P} be a Poincaré map generated on the plane by Eq. 25, they prove that:

Theorem 5.4. *For all parameter values in a sufficiently small neighborhood of parameter value given by Eq. 26, there exists a transversal section $I \subset \Sigma$ such that the Poincaré map \mathbf{P} induced by Eq. 25 is well defined and continuous on I . There exists a continuous surjective map $\pi : \text{Inv}(I, \mathbf{P}^2) \rightarrow \Sigma_2$, such that*

$$\pi \circ \mathbf{P}^2 = \sigma \circ \sigma$$

The preimage of any periodic sequence from Σ_2 contains periodic points of \mathbf{P}^2 .

Remark 5.2. The maximal invariant part of I (with respect to \mathbf{P}^2) is defined by

$$\text{Inv}(I, \mathbf{P}^2) = \bigcap_{i \in \mathbb{Z}} \mathbf{P}_{|I}^{-2i}(I)$$

and $\Sigma_2 = \{0, 1, \dots, K-1\}^{\mathbb{Z}}$ is a topological space with the Tichonov topology; $0, 1, \dots, K-1$ being symbols characterizing periodic infinite sequences of TS-maps (see⁴ fore more details).

In this case the Poincaré map is issued directly from Lorenz equations not from the geometric model. Due to the limited extend of this article, we do not cite all the results on computer aided proof. We refer the reader to.⁴

5.4. Rössler attractor (1976)

We have seen that from the seminal discovery of the Lorenz attractor, several strategies have been developped in order to study this appealing and complex mathematical object: geometric Lorenz model, Lorenz map, Hénon map (and Lozi map as linearized version). In 1976 O. E. Rössler followed a different direction of research: instead of simplify the mathematic equation 25 and considering that, due to extreme simplification, there is no actual link between this equation and the Rayleigh-Benard problem from which it is originate, he turned his mind to the study of a chemical

Figure 21. Rössler attractor.

multi-vibrator. He started to design some three-variable oscillator based on a two-variable bistable system coupled to a slowly moving third-variable. The resulting three-dimensional system was only producing limit cycles at the time. At an international congress on rhythmic functions held on September 8-12, 1975 in Vienna, he met A. Winfree, a theoretical biologist who challenged him to find a biochemical reaction reproducing the Lorenz attractor. Rössler failed to find a chemical or biochemical reaction producing the Lorenz attractor but, he instead found a simpler type of chaos in a paper he wrote during the 1975 Christmas holidays.⁵⁵ The obtained chaotic attractor (see Fig. 21)

$$\begin{cases} \dot{x} = -y - z \\ \dot{y} = x + ay \\ \dot{z} = b + z(x - c) \end{cases} \quad (28)$$

$$a = 0.2, \quad b = 0.2, \quad c = 5.7 \quad (29)$$

does not have the rotation symmetry of the Lorenz attractor (defined by Eq. 27), but it is characterized by a map equivalent to the Lorenz map.

The reaction scheme (see Fig. 22) leading to Eq. 28 is meticulously analyzed by Ch. Letellier and V. Messenger.⁵⁶

The structure of the Rössler attractor is simpler than the Lorenz's one. However even if hundreds of papers has been written on it, the rigorous proof of its existence is not yet established as done for Lorenz equations. In 1997, P. Zygliczyński using reduced Rössler equations to two parameters instead of three (i. e. stating that

Figure 22. Combination of an Edelstein switch with a Turing oscillator in a reaction system producing chaos. E = switching subsystem, T = oscillating subsystem; constant pools (sources and sinks) have been omitted from the scheme as usual (From,⁵⁶ adapted from.⁵⁵)

$a = b$ in Eq. 28) gave, using computer assisted proof similar results as he did for Lorenz equations.⁴

$$\text{Let } \Theta = \left\{ (x, y, z) \in \mathbb{R}^3; x = 0, y < 0, \dot{x} > 0 \right\}$$

Theorem 5.5. *For all parameter values in a sufficiently small neighborhood of $(a, c) = (0.2, 5.7)$ there exists a transversal section $N \subset \Theta$ such that the Poincaré map \mathbf{P} induced by Eq. 28 is well defined and continuous. There exists a continuous surjective map $\pi : \text{Inv}(N, \mathbf{P}) \rightarrow \Sigma_3$, such that*

$$\pi \circ \mathbf{P} = \sigma \circ \pi$$

$\Sigma_A \subset \pi(\text{Inv}(N, \mathbf{P}))$, where

$$A = \begin{bmatrix} 0 & 1 & 1 \\ 0 & 1 & 1 \\ 1 & 0 & 0 \end{bmatrix}$$

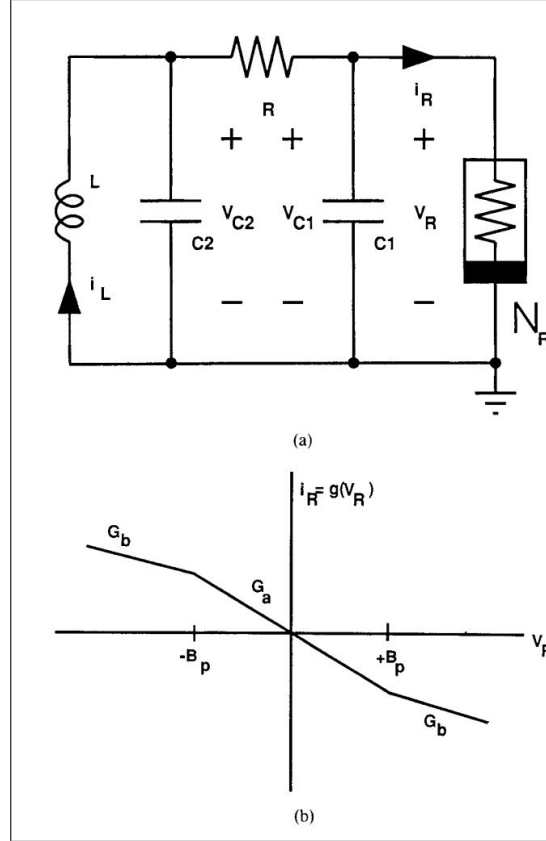

The preimage of any periodic sequence from Σ_A contains periodic points of \mathbf{P} .

As this result is related to the Poincaré map of Rössler equations, nowadays there is still a need to apply the method developed by W. Tucker to prove the true existence of a strange attractor.

5.5. *Chua attractor (1983)*

Before he discovered his equations, O. Rössler in collaboration with F. Seelig, inspired by a little book entitled *Measuring signal generators, Frequency Measuring Devices and Multivibrators from the Radio-Amateur Library*,⁵⁷ began to “translate” electronic systems into nonlinear chemical reaction systems. The know-how he developed led eventually in to his chaotic model. Few years later, in October 1983, visiting T. Matsumoto at Waseda University, L. O. Chua found an electronic circuit (see Fig. 23) mimicking directly on an oscilloscope screen a chaotic signal (see Fig. 24). As we have seen, only two autonomous systems of ordinary differential equations were generally accepted then as being chaotic, the Lorenz equations and the Rössler equations. The nonlinearity in both systems is a function of two variables namely, the product function which is very difficult to build in electronic circuit. L. O. Chua⁵⁸ says, “I was to have witnessed a live demonstration of presumably the world’s first successful electronic circuit realization of the Lorenz Equations, on which Professor Matsumoto’s research group had toiled for over a year. It was indeed a remarkable piece of electronic circuitry. It was painstakingly breadboarded to near perfection, exposing neatly more than a dozen IC components, and embellished by almost as many potentiometers and trimmers for fine tuning and tweaking their incredibly sensitive circuit board. There would have been no need for inventing a more robust chaotic circuit had Matsumoto’s Lorenz Circuit worked. **It did not.** The fault lies on the dearth of a critical nonlinear IC component with a near-ideal characteristic and a sufficiently large dynamic range; namely, the analog multiplier. Unfortunately, this component was the key to building an autonomous chaotic circuit in 1983.” He adds, “Prior to 1983, the conspicuous absence of a reproducible functioning chaotic circuit or system seems to suggest that chaos is a pathological phenomenon that can exist only in mathematical abstractions, and in computer simulations of contrived equations. Consequently, electrical engineers in general, and nonlinear circuit theorists in particular, have heretofore paid little attention to a phenomenon which many had regarded as an esoteric curiosity. Such was the state of mind among the nonlinear circuit theory community, circa 1983. Matsumoto’s Lorenz Circuit was to have turned the tide of indifference among nonlinear circuit theorists. Viewed from this historical perspective and motivation, the utter disappointments that descended upon all of us on that uneventful October afternoon was quite understandable. So profound was this failure that the wretched feeling persisted in my subconscious mind till about bedtime that evening. Suddenly it dawned upon me that since the main mechanism which gives rise to chaos, in both the Lorenz and the Rössler Equations, is the presence of at least two unstable equilibrium points - 3 for the Lorenz Equations and 2 for the Rössler Equations - it seems only prudent to design a simpler and more robust circuit having these attributes.

Having identified this alternative approach and strategy, it becomes a simple exercise in elementary nonlinear circuit theory to enumerate systematically all such

Figure 23. Chua's circuit from.⁶¹

circuit candidates, of which there were only 8 of them, and then to systematically eliminate those that, for one reason or another, can not be chaotic.”

The Chua's equations

$$\begin{cases} \dot{x} = \alpha(y - \Phi(x)) \\ \dot{y} = x - y + z \\ \dot{z} = -\beta y \end{cases} \quad (30)$$

$$\Phi(x) = x + g(x) = m_1 x + \frac{1}{2} (m_0 - m_1) [|x + 1| - |x - 1|] \quad (31)$$

$$\alpha = 15.60, \beta = 28.58, m_0 = -\frac{1}{7}, m_1 = \frac{2}{7} \quad (32)$$

where soon carefully analyzed by T. Matsumoto.⁵⁹ The main mathematical idea underneath behind the invention of this circuit is the same one as simplifying the

Figure 24. Chua attractor.

Hénon map by linearizing the parabola with an absolute value as done in Lozi map six years before (even if L. O. Chua did not know these maps at that time).

The “nonlinear” characteristic which is in fact only piecewise linear allows some exact computations. Henceforth, L. O. Chua et al. proved very soon that the mechanism of chaos exists in this attractor.⁶⁰ However in spite it is possible to obtain closed formula for the solution of Eqs. 30 in every subspace $\{x \leq -1\}, \{-1 < x < 1\}, \{1 \leq x\}$, due to the transcendental nature of the equation allowing the computation at the matching boundaries $\{x = -1\}, \{x = 1\}$, of the global solution,⁹ it is not possible to compute it explicitly. As only numerically computed solutions are available, it remains the gnawing problem of what is really computed. To that problem may be added the fact that the electronic realization of the Chua’s circuit is not exactly governed by Eqs. 30, due to the instability of the electronics components, the parameter value (Eq. 32) is randomly fluctuating around its mean value. It is very difficult to analyze the experimental observed chaos.⁶¹

One possible way to perform this analysis may be the use of a new mathematical tool: *confinor* instead of *attractor*.⁶² The *confinor* theory, when applied to Chua’s circuit allowed the discovery of coexisting chaotic regimes.^{8,63}

6. conclusion

We have shown, in the limited extend of this article, on few but well known examples,¹⁰ that it is very difficult to trust in numerical solution of chaotic dynamical dissipative systems. In some cases one can even proof that it is never possible to

obtain reliable results. We have focused our survey on models related to the seminal Lorenz model which is the most studied model of strange attractor. These models are not the only one studied today. Countless models presenting chaos, arising in every fields concerned with dynamics such as ecology, biology, chemistry, economy, finance, electronics ..., are developed since forty years. However their study is less carefully done as those presented here, conducting sometimes to hasty results and flawed theories in these sciences. In addition the disturbing phenomenon of “ghost solution” can appear when discretization of nonlinear differential equation by central difference scheme is used (several examples of such ghost solutions when central difference scheme is used sole or in combination with Euler’s scheme, are given by M. Yamaguti and al.⁶⁴). Recently A. N. Sharkovsky and S. A. Berezovsky⁶⁵ pointed out the notion of “numerical turbulence” which appears, due to incorrectness of calculation method stipulated by discreteness. In conclusion one can say that there is room for more study of the relationship between numerical computation and theoretical behavior of chaotic solutions of dynamical systems.
